Incidental Parameters and Dynamic Bias in Panel Data

In the previous lecture we found that (apparently) $\hat{\beta}_w$ was safe in the sense that it provided a consistent estimate of the parameters as $T \to \infty$ and $n \to \infty$ regardless of whether there was correlation between individual effects and the included explanatory variables. The situation is less comforting when $T$ is fixed and $n \to \infty$ as we might view as typical in many econometric panel data problems. (expanding $n$ is relatively easy, expanding $T$ is usually not.) Chamberlain (1980) and Nickell (1981) consider the following model:

$$y_{it} = \gamma y_{it-1} + \alpha_i + u_{it}$$

then the within estimator is

$$\hat{\gamma}_w = \frac{\sum \sum (y_{it} - \bar{y}_t)(y_{it-1} - \bar{y}_{t-1})}{\sum \sum (y_{i,t-1} - \bar{y}_{i,t-1})^2} = \sum \sum w_{it}(y_{it} - \bar{y}_t)$$

$$= \gamma + \sum \sum (u_{it} - \bar{u}_i)w_{it}$$

repeatedly substituting we have,

$$y_{it} = u_{it} + \gamma u_{it-1} + \cdots + \gamma^{i-1} u_{i1} + \gamma^i y_{i0} + \frac{1 - \gamma^i}{1 - \gamma} \alpha_i$$

so

$$\sum_{t=1}^{T} y_{it-1} = (1 + \gamma + \gamma^2 + \cdots + \gamma^{T-1})y_{i0} + \left(\frac{T - 1 - T\gamma + \gamma^T}{(1 - \gamma)^2}\right) \alpha_i$$

$$+ \frac{1 - \gamma^{T-1}}{1 - \gamma} u_{i1} + \frac{1 - \gamma^{T-2}}{1 - \gamma} u_{i2} + \cdots + u_{iT-1}.$$ 

Similar computations for the denominator of $\hat{\gamma}_w$ eventually yield

$$\hat{\gamma}_w \to \gamma - \frac{1 - \gamma}{T - 1} \left(1 - T^{-1} \frac{1 - \gamma^T}{1 - \gamma}\right) \left\{1 - \frac{2\gamma}{(1 - \gamma)(T - 1)} \left[1 - \frac{1 - \gamma^T}{T(1 - \gamma)}\right]^{-1}\right\}$$

bias
Thus for example we have in the simple version of the model with $\gamma = .5$,

$T = 2 \quad \text{ABias} = -(1 + \gamma)/2 \quad -3/4$

$T = 3 \quad \text{ABias} = -(2 + \gamma)(1 + \gamma)/(2(3 + \gamma)) \quad -.53$

$T = 10 \quad \text{bias} \quad -.16$

These asymptotic biases are obviously very large relative to the true $\gamma = .5$.

There is an emerging consensus that the best approach to dealing with the problems we have just seen in dynamic panel data models is based on generalized method of moments (GMM) methods. We are already familiar with many important examples of GMM, although we may not have explicitly recognized this. For example, my usual simplified derivation of OLS and IV estimators proceeds by first assuming we have an orthogonality condition between observed $x$’s and unobserved $u$’s, and then impose this orthogonality on the sample to get OLS:

$$EX'u = 0 \Rightarrow X'\hat{u} = 0 \Rightarrow \hat{\beta} = (X'X)^{-1}X'y$$

In the instrumental variables version of this, $X$ isn’t orthogonal to $u$, but we have exactly the right number of IV’s, say $Z$, and we obtain

$$EZ'u = 0 \Rightarrow Z'\hat{u} = 0 \Rightarrow \hat{\beta} = (Z'X)^{-1}Z'y$$

and finally, if we have too many IV’s we would like to impose the orthogonality condition $EZ'u = 0$ on the sample, but $Z'\hat{u} = 0$ in this case is expecting us to solve $q > p$ equations in only $p$ unknowns, which is not generally feasible, so we need a new idea.

One approach which suggests itself is to minimize the length of the vector $Z'\hat{u}$. This sounds reasonable and is also suggested by least squares ideas, so we would solve

$$\min_\hat{b} \hat{u}(\hat{b})'ZZ'\hat{u}(\hat{b})$$

which yields

$$\hat{\beta} = (X'ZZ'X)^{-1}X'ZZ'y$$

What is wrong with this? What is missing if we want to get 2SLS? How do we rationalize the 2SLS choice

$$\hat{\beta} = (X'P_zX)^{-1}X'P_zy$$

Well, let’s work backward. We see immediately that if we had minimized instead,

$$\min_\hat{b} \hat{u}(\hat{b})'Z(Z'Z)^{-1}Z'\hat{u}(\hat{b}),$$
we would get 2SLS, does this make any particular sense? Maybe.

Suppose we had something like the following

\[ M(\theta) \sim \mathcal{N}(0, V) \]

for example \( M(\theta) = M \theta \), and we wanted to estimate \( \theta \) with \( V \) known. What would we do? What might be the argument for solving

\[ \min_{\theta} M(\theta)'V^{-1}M(\theta) \]

Suppose, first that \( V \) were diagonal, then this would weight the coordinates so that they all had \( \chi^2 \) behavior. A better, more general, idea would be to say “let’s think of this as nonlinear regression.”

The model is then,

\[ y_i = M_i(\theta) + v_i \quad i = 1, \ldots, P \]

where \( Evv' = V \), so the GLS estimator minimizes the weighted sum of squares.

Now in the 2SLS context we need to compute \( V = V(Z'u) \). This is easy if we assume that \( E(uu'|Z) = \sigma^2I \) as usual, then we get

\[ V = V(Z'u) = E(Z'u'u)Z = \sigma^2Z'Z, \]

so we do indeed get back to 2SLS, by taking this route. Note that if \( E(uu'|Z) = \Omega \), then we get the GIVE estimate, as discussed in an earlier lecture.

This justifies GMM as GLS for a nonlinear regression model. Note that the assumption of exact normality is rather implausible, but approximate normality is easy to justify since one would hope/expect that

\[ n^{-1/2}Z'u \]

would satisfy conditions for a CLT. So in practice, we have approximate normality and we solve

\[ \min_{\theta} M(\theta)'V_n^{-1}M(\theta) \]

where \( V_n \to V \) in probability.

Now, in considerably more general situations than 2SLS we may think of orthogonality conditions generating a set of \( I \) conditions

\[ M(\theta) = 0 \]

with \( V = EM M' \) and we can, on the same principle as we have just developed suggest using

\[ \hat{\theta} = \arg \min_{\theta} M(\theta)'V^{-1}M(\theta) \]
Suppose we had some consistent estimator of $\theta$, say $\hat{\theta}_0$, then by Taylor expansion

$$M(\theta) = M(\hat{\theta}_0) + (\theta - \hat{\theta}_0)'\nabla M(\hat{\theta}_0)$$

and a one-step estimation of $\theta$ would minimize

$$\min_{\hat{\theta}} (M(\hat{\theta}_0) - \nabla M(\hat{\theta}_0)'(\theta - \hat{\theta}_0)V^{-1}(M(\hat{\theta}_0) - \nabla M(\hat{\theta}_0)(\theta - \hat{\theta}_0)))$$

$$\Rightarrow \hat{\theta}_1 = \hat{\theta}_0 + (\nabla M'V^{-1}\nabla M)^{-1}\nabla M V^{-1} M(\hat{\theta}_0).$$

We could continue to iterate this solution, which would yield (eventually) a solution to the original problem.

Now, we are ready to consider the use of GMM methods in panel data. To fix some ideas, consider our very simple dynamic panel model

$$y_{it} = \alpha y_{i(t-1)} + \eta_i + \nu_{it}$$

where $E\nu_{it}\nu_{is} = 0$ for $t \neq s$. We are interested in estimating the vector $\alpha$ and to do so we would like to find an exhaustive list of available, valid moment conditions.

The first problem is that the $\eta_i$’s generate dependence over time, the second problem is that if we pursue the HT strategy of applying the Q transformation to get rid of $\eta_i$, we lose the time-series structure of the data. What to do? Consider first differencing the data. We get

$$\Delta y_{it} = \alpha \Delta y_{i(t)} + \Delta \nu_{it}$$

But if the $\nu_{it}$ are iid, then $y_{i(t-2)}$ is independent of $\Delta \nu_{it}$, and so is $y_{i(t-3)}$, etc. So we may collect these conditions to write

$$E[(\Delta y_{it} - \alpha \Delta y_{i(t-1)})y_{i(t-j)}] = 0$$

$$t = 3, \ldots, T; \quad j = 2, \ldots, t - 1$$

From these conditions we may design an estimator à la GMM. Anderson and Hsiao (1981) suggest estimating (s) by IV using either $y_{i(t-2)}$ or $\Delta y_{i(t-2)}$ as an IV. Since we obviously have more serviceable instruments it (may) make sense to use more instruments. AB(1991) suggests using all the $\perp$ conditions and GMM.

They write

$$Z_i = \left(\begin{array}{c} y_{i1} \\ \left( y_{i1}, y_{i2} \right) \\ \vdots \\ \cdots \left( y_{i1}, y_{i2}, \ldots, y_{i(T-2)} \right) \end{array}\right)$$
\[(T - 2) \times (m = (T - 2)(t - 1)/2)\]

Note that \(1 + 2 + \ldots + (T - 2) = m\). And

\[
\tilde{v}_i = \begin{pmatrix} \Delta v_{i3} \\ \Delta v_{i4} \\ \vdots \\ \Delta v_{iT} \end{pmatrix}.
\]

The conditions say that

\[EZ_i'\tilde{v}_i = 0\]

so GMM suggests that we minimize

\[
\left(\sum_{i=1}^{n} \tilde{v}_i(\alpha)'Z_i\right)A_n\left(\sum_{i=1}^{n} Z_i'\tilde{v}_i(\alpha)\right)
\]

for some appropriate choice of \(A_n\). Which one? This would yield the estimator (4) in AB (1991)

\[
\hat{\alpha} = \frac{\Delta y_{-1}ZA\Delta y}{\Delta y_{-1}ZAZ'\Delta y_{-1}}
\]

Consider \(V(n^{-1} \sum Z_i'\tilde{v}_i) = n^{-1} \sum Z_i(E\tilde{v}_i\tilde{v}_i')Z_i\) where

\[
E\tilde{v}_i\tilde{v}_i' = \sigma^2_n \begin{pmatrix} 2 & -1 \\ -1 & 2 & -1 \\ & \ddots & \ddots & \ddots \\ & & \ddots & -1 & 2 \end{pmatrix}
\]

Since

\[
E\tilde{v}_{it}\tilde{v}_{it} = E(v_{it} - v_{it-1})(v_{it} - v_{it-1}) = E\tilde{v}_i^2 - 2v_{it}v_{it-1} + v_{it-1}^2 = 2\sigma^2_v
\]

\[
E\tilde{v}_{it}\tilde{v}_{it-1} = E(v_{it} - v_{it-1})(v_{it-1} - v_{it-2}) = -\sigma^2_v
\]

If there is heteroscedasticity, then things are more complicated. Of course

\[E\tilde{v}_{it}\tilde{v}_{it-s} = 0 \quad \text{for} \ s \geq 2.\]
This gives a one-step estimator. A two-step estimator may be constructed using the White type estimator,

\[ \hat{V}_n = n^{-1} \sum Z_i^\prime \hat{e}_i^\prime \hat{e}_i Z_i \]

In effect these estimators are like the Anderson-Hsiao estimator, but (i) They use more IV’s (ii) They use a better \( \hat{V}_n \). It is interesting to consider how the number of IV’s grows with \( T \) in the AB model. A simple computation yields the following table which describes the situation

<table>
<thead>
<tr>
<th></th>
<th>3</th>
<th>6</th>
<th>10</th>
<th>20</th>
</tr>
</thead>
<tbody>
<tr>
<td>( q )</td>
<td>1</td>
<td>10</td>
<td>36</td>
<td>171</td>
</tr>
<tr>
<td>( n )</td>
<td>20</td>
<td>20000</td>
<td>933000</td>
<td>100000000</td>
</tr>
<tr>
<td>( N )</td>
<td>7</td>
<td>3333</td>
<td>9300</td>
<td>5000000</td>
</tr>
</tbody>
</table>

It is reasonably straightforward to consider adding exogenous variables. Consider

\[ y_{it} = \alpha y_{i,t-1} + x_{it}^\prime \beta + \eta_i + u_{it} \]

if we don’t wish to assume \( x_{it} \perp \eta_i \), then we get \( Z \) like previous case except that in addition to \( y_{it}, \ldots, y_{is} \) we have \( x_{i1}, \ldots, x_{is+1} \). for predetermined \( x \)’s and \( x_{i1} \ldots x_{iT} \) for strictly exogenous \( x \)’s. More generally, as in HT, we could partition \( x \)’s into \( x_1, x_2 \) with \( x_1 \perp \eta \), then we get even more \( \perp \) conditions which could be exploited.
